Abstract—Detecting anomalous events in online computer systems is crucial to protect the systems from malicious attacks or malfunctions. System logs, which record detailed information of computational events, are widely used for system status analysis. In this paper, we propose LogBERT, a self-supervised framework for log anomaly detection based on Bidirectional Encoder Representations from Transformers (BERT). LogBERT learns the patterns of normal log sequences by two novel self-supervised training tasks, masked log message prediction and volume of hypersphere minimization. After training, LogBERT is able to capture the patterns of normal log sequences and further detect anomalies where the underlying patterns deviate from expected patterns. The experimental results on three log datasets show that LogBERT outperforms state-of-the-art approaches for anomaly detection.

I. INTRODUCTION

Online computer systems are vulnerable to various malicious attacks in cyberspace. Detecting anomalous events from online computer systems in a timely manner is the fundamental step to protect the systems from attacks or malfunctions. System logs, which record detailed information about computational events generated by computer systems, play an important role in anomaly detection nowadays.

Currently, many traditional machine learning models are proposed for identifying anomalous events from log messages. These approaches extract useful features from log messages and adopt machine learning algorithms to analyze the log data [1]. Due to the data imbalance issue, it is hard to train a binary classifier to detect anomalous log sequences in a supervised learning setting. As a result, many unsupervised learning models, such as Principal Component Analysis (PCA) [2], or one class classification models, such as one-class SVM [3], [4], are adopted to detect anomalies. However, traditional machine learning models, which are based on hand-craft features, are infeasible to capture the temporal information of discrete log messages.

Recently, deep learning models, especially recurrent neural networks (RNNs), are widely used for log anomaly detection since they are able to capture the temporal information in sequential data [5], [6], [7]. However, there are still some limitations of using RNN for modeling log data. First, the traditional RNN cannot encode the context information of a log sequence from both the left and right context. However, it is crucial to observe the complete context information instead of only the information from previous steps when detecting malicious attacks based on log messages. Although

a Bidirectional RNN is commonly used nowadays to capture the contextual information, which consists of two hidden layers that pass information in both forward and backward directions, it still faces the problem of vanishing or exploding gradients, which means the model is hard to capture the long term dependency. Because log sequences usually consist of many log messages, capturing the long term dependency is critical for detecting the anomalies. Second, current RNN-based anomaly detection models are trained to capture the patterns of normal sequences by prediction the next log message given previous log messages. This training objective mainly focuses on capturing the correlation among the log messages in normal sequences. When such correlation in a log sequence is violated, the RNN model cannot correctly predict the next log message based on previous ones. Then, we will label the sequence as anomalous. However, only using the prediction of next log message as objective function cannot not explicitly encode the common patterns shared by all normal sequences.

To tackle the existing limitations of RNN-based models, in this work, we propose LogBERT, a self-supervised framework for log anomaly detection based on Bidirectional Encoder Representations from Transformers (BERT). Inspired by the great success of BERT in modeling sequential text data [8], we leverage BERT to capture patterns of normal log sequences. By using the structure of BERT, we expect the contextual embedding of each log entry can capture the information of whole log sequences with various lengths. In order to train LogBERT for anomalous sequence detection with the consideration of the shortage of anomalous data, we propose two self-supervised training tasks: 1) masked log message prediction, which aims to correctly predict log messages in normal log sequences that are randomly masked; 2) volume of hypersphere minimization, which aims to make the normal log sequences close to each other in the embedding space. By training to predict the randomly masked log messages, we expect BERT is able to capture the correlation among log messages so that an anomalous log sequence that violates such correlation can be detected. Moreover, by minimizing the volume of the hypersphere, we can force the BERT model to capture some common patterns from various normal log sequences because the model is trained to map the log sequences into the center of the hypersphere. Then, the anomalous log sequences that do not have the common patterns will be far from the center of hypersphere. After training, we expect LogBERT encodes

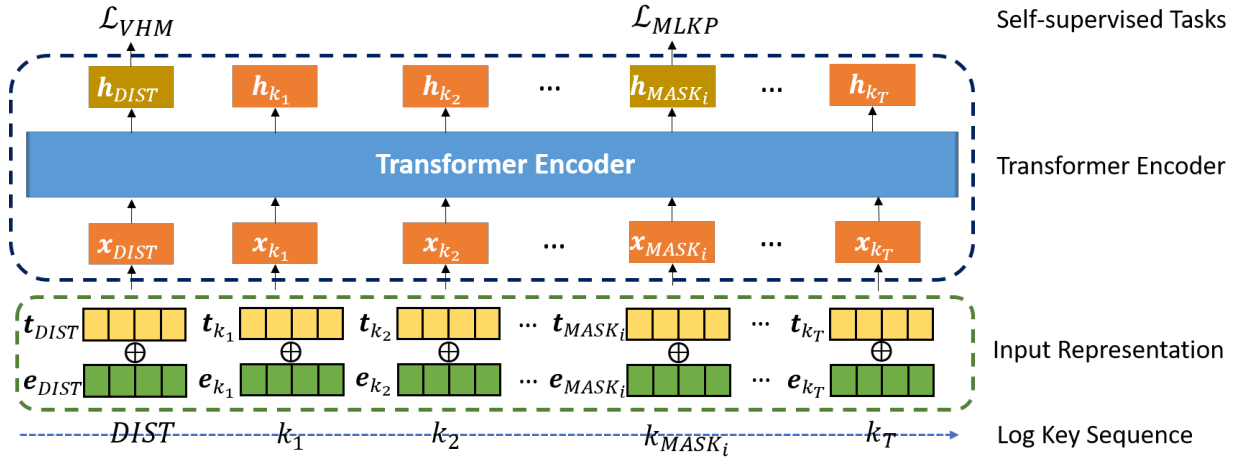

Fig. 1: The overview of LogBERT

the information about normal log sequences and then derive a criterion to detect anomalous log sequences. Experimental results on three log datasets show that LogBERT achieves the best performance on log anomaly detection by comparing with various state-of-the-art baselines.

II. RELATED WORK

System logs are widely used by large online computer systems for troubleshooting, where each log message is usually a semi-structured text string. The traditional approaches explicitly use the keywords (e.g., “fail”) or regular expressions to detect anomalous log entries. However, these approaches cannot detect malicious attacks based on a sequence of operations, where each log entry looks normal, but the whole sequence is anomalous. To tackle this challenge, many rule-based approaches are proposed to identify anomalous events [9], [10]. Although rule based approaches can achieve high accuracy, they can only identify pre-defined anomalous scenarios and require heavy manual engineering. Once attackers conduct new types of attacks, the rule-based approaches cannot achieve good performance.

As malicious attacks become more complicated, various learning-based approaches are proposed. The typical pipeline for these approaches consists of three steps [11]. First, a log parser is adopted to transform log messages to log keys. A feature extraction approach, such as TF-IDF, is then used to build a feature vector to represent a sequence of log keys in a sliding window. Based on the extracted feature vectors, some supervised learning approaches, such as decision tree or SVM, are used to detect the anomalous sequences [11]. However, due to the scarcity of anomalous sequences, manually collecting and labeling large amounts of anomalous data is not practical. Hence, in most cases, an unsupervised approach is applied for detecting the anomalous sequences [12], [13]. The major limitation of the traditional machine learning methods is that they cannot capture the temporal information from the sequence data.

Recently, many deep learning-based log anomaly detection approaches are proposed for log anomaly detection [14], [5], [15], [6], [16], [7]. Most of the existing approaches adopt recurrent neural networks (RNNs), especially long-short term memory (LSTM) or gated recurrent unit (GRU) to model the normal log key sequences and derive anomalous scores to detect the anomalous log sequences [5], [6], [7]. The main idea of the existing work is to adopt RNN to predict the next possible log message based on previous messages in a sequence. An anomalous sequence will be detected if the actual message is out of a candidate set of expected normal log messages. A recent study builds a graph based on log sequences and leverages the graph embedding approach to detect the anomalies [16]. In this work, we explore the advanced BERT model to capture the information of log sequences and propose two novel self-supervised tasks to train the model.

III. LOGBERT

In this section, we introduce our framework, LogBERT, for log sequence anomaly detection. Inspired by BERT [8], LogBERT leverages the Transformer encoder to model log sequences and is trained by novel self-supervised tasks to capture the patterns of normal sequences. Figure 1 shows the whole framework of LogBERT.

A. Framework

Given a sequence of unstructured log messages, we aim to detect whether this sequence is normal or anomalous. In order to represent log messages, following a typical pre-processing approach, we first extract log keys (string templates) from log messages via a log parser (shown in Figure 2). Then, we can define a log sequence as a sequence of ordered log keys $S = \{k_1, \dots, k_t, \dots, k_T\}$, where $k_t \in \mathcal{K}$ indicates the log key in the t -th position, and \mathcal{K} indicates a set of log keys extracted from log messages. The goal of this task is to predict whether a new log sequence S is anomalous based on a training dataset $\mathcal{D} = \{S^j\}_{j=1}^N$ that consists of only normal log sequences.

Fig. 2: Log messages in the BGL dataset and the corresponding log keys extracted by a log parser. The message with red underline indicates the detailed computational event.

To achieve that, LogBERT is trained to model the normal sequences and further derives an anomaly detection criterion to identify anomalous sequences.

Input Representation. Given a normal log sequence S^j , we first add a special token, DIST, at the beginning of $S^j = \{k_1^j, \dots, k_t^j, \dots, k_T^j\}$ as the first log key, which is used to represent the whole log sequence based on the structure of Transformer encoder. We will use the contextual embedding of DIST to constraint the distribution of normal log sequences. LogBERT then represents each log key k_t^j as an input representation \mathbf{x}_t^j , where the representation \mathbf{x}_t^j is a summation of a log key embedding and a position embedding. The purpose of log key embeddings is to map the log keys into an embedding space. In this work, we adopt a matrix $\mathbf{E} \in \mathbb{R}^{|\mathcal{K}| \times d}$ as the log key embedding matrix, where d is the dimension of log key embedding.

Different from RNN, the Transformer encoder does not have a recurrent structure. In order to model the order information in a sequence, Transformer encoder adopts the position embeddings to inject the position information of log keys in the sequence. We denote the position embeddings as $\mathbf{T} \in \mathbb{R}^{T \times d}$, which has the same dimension as the log key embeddings. Especially, we adopt the same sinusoid function as the position encoding in [17] to generate the position embeddings, which are defined as $\mathbf{T}_{t,2i} = \sin(t/10000^{2i/d})$; $\mathbf{T}_{t,2i+1} = \cos(t/10000^{2i/d})$, where t is the t -th position in a sequence; i is the i -th dimension of the d -dimensional embedding. The advantage of using sinusoid function is that it allows the model to easily learn to attend by relative positions, since for any fixed offset k , \mathbf{T}_{t+k} can be represented as a linear function of \mathbf{T}_t .

Finally, the input representation of the log key k_t is defined as:

$$\mathbf{x}_t^j = \mathbf{e}_{k_t^j} + \mathbf{t}_{k_t^j}. \quad (1)$$

Transformer Encoder. LogBERT adopts Transformer encoder to learn the contextual relations among log keys in a sequence. Transformer encoder consists of multiple transformer layers. Each transformer layer includes a multi-head self-attention sub-layer and a position-wise feed forward sub-layer, in which a residual connection is employed around each of two sub-layers, followed by layer normalization [17]. The multi-head attention employs H parallel self-attentions to jointly capture different aspect information at different positions over the input log sequence. Formally, for the l -th head of the attention layer, the scaled dot-product self-attention is defined

as:

$$\text{head}_l = \text{Attention}(\mathbf{X}^j \mathbf{W}_l^Q, \mathbf{X}^j \mathbf{W}_l^K, \mathbf{X}^j \mathbf{W}_l^V), \quad (2)$$

where $\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\frac{\mathbf{QK}^T}{\sqrt{d_v}})\mathbf{V}$; $\mathbf{X}^j \in \mathbb{R}^{T \times d}$ is the input representation of the log sequence; \mathbf{W}_l^Q , \mathbf{W}_l^K and \mathbf{W}_l^V are linear projection weights with dimensions $\mathbb{R}^{d \times d_v}$ for the l -th head, and d_v is the dimension for one head of the attention layer. Each self-attention makes each key attend to all the log keys in an input sequence and computes the hidden representation for each log key with an attention distribution over the sequence. Based on the attention mechanism, LogBERT is able to capture the long-term dependency among log keys.

The multi-head attention employs a parallel of self-attentions to jointly capture different aspect information at different log keys. Formally, the multi-head attention concatenates H parallel heads together as:

$$f(\mathbf{X}^j) = \text{Concat}(\text{head}_1, \dots, \text{head}_H) \mathbf{W}^O, \quad (3)$$

where $\mathbf{W}^O \in \mathbb{R}^{hd_v \times d_o}$ is a projection matrix, and d_o is the dimension for the output of multi-head attention sub-layer.

Then, the position-wise feed forward sub-layer with a ReLU activation is applied to the hidden representation of each activity separately. Finally, by combining the position-wise feed forward sub-layer and multi-head attention, a transformer layer is defined as:

$$\begin{aligned} \text{transformer_layer}(\mathbf{X}^j) &= \text{FFN}(f(\mathbf{X}^j)) \\ &= \text{ReLU}(f(\mathbf{X}^j) \mathbf{W}_1) \mathbf{W}_2, \end{aligned} \quad (4)$$

where \mathbf{W}_1 and \mathbf{W}_2 are trained projection matrices.

The Transformer encoder usually consists of multiple transformer layers. We denote \mathbf{h}_t^j as the contextual embedding vector of the log key k_t^j produced by the Transformer encoder, i.e.,

$$\mathbf{h}_t^j = \text{Transformer}(x_t^j). \quad (5)$$

B. Objective Function

In order to train the LogBERT model, we propose two self-supervised training tasks to capture the patterns of normal log sequences.

Task I: Masked Log Key Prediction (MLKP). In order to capture the bidirectional context information of log sequences, we train LogBERT to predict the masked log keys in log sequences. In our scenario, LogBERT takes log sequences with random masks as inputs, where we randomly replace a ratio of log keys in a sequence with a specific MASK token.

The training objective is to accurately predict the randomly masked log keys. The purpose is to make LogBERT encode the correlation among log keys in normal log sequences.

To achieve that, we feed the contextual embedding vector of the i -th MASK token in the j -th log sequence $\mathbf{h}_{[\text{MASK}_i]}^j$ to a softmax function, which will output a probability distribution over the entire set of log keys \mathcal{K} :

$$\hat{\mathbf{y}}_{[\text{MASK}_i]}^j = \text{Softmax}(\mathbf{W}_C \mathbf{h}_{[\text{MASK}_i]}^j + \mathbf{b}_C), \quad (6)$$

where \mathbf{W}_C and \mathbf{b}_C are trainable parameters. Then, we adopt the cross entropy loss as the objective function for masked log key prediction, which is defined as:

$$\mathcal{L}_{MLKP} = -\frac{1}{N} \sum_{j=1}^N \sum_{i=1}^M \mathbf{y}_{[\text{MASK}_i]}^j \log \hat{\mathbf{y}}_{[\text{MASK}_i]}^j, \quad (7)$$

where $\mathbf{y}_{[\text{MASK}_i]}^j$ indicates the real log key for the i -th masked token, and M is the total number of masked tokens in the j -th log sequence.

Once LogBERT is able to correctly predict the masked log keys in normal sequences, it indicates LogBERT captures the correlation among log keys. Because the correlation among log keys in an anomalous log sequence is different from that of in normal log sequences, LogBERT cannot correctly predict the masked log keys in an anomalous sequence. Hence, we expect after training, LogBERT can distinguish the normal and anomalous log sequences.

Task II: Volume of Hypersphere Minimization (VHM). Inspired by the Deep SVDD approach [18], where the objective is to minimize the volume of a data-enclosing hypersphere, we propose a spherical objective function to regulate the distribution of normal log sequences. The motivation is that normal log sequences should be concentrated and close to each other in the embedding space, while the anomalous log sequences are far to the center of the sphere. We first derive the representations of normal log sequences and then compute the center representation based on the mean operation. In particular, we consider the contextual embedding vector of the DIST token $\mathbf{h}_{\text{DIST}}^j$, which encodes the information of entire log sequence based on the Transformer encoder, as the representation of a log sequence in the embedding space. To make the representations of normal log sequences close to each other, we further derive the center representation of normal log sequences \mathbf{c} in the training set by a mean operation, i.e., $\mathbf{c} = \text{Mean}(\mathbf{h}_{\text{DIST}}^j)$. Then, the objective function is to make the representation of normal log sequence $\mathbf{h}_{\text{DIST}}^j$ close to the center representation \mathbf{c} :

$$\mathcal{L}_{VHM} = \frac{1}{N} \sum_{j=1}^N \|\mathbf{h}_{\text{DIST}}^j - \mathbf{c}\|^2. \quad (8)$$

By minimizing the Equation 8, we expect the center \mathbf{c} could encode the extracted common patterns from normal log sequences. As a result, after training, all the normal log sequences in the training set should be close to the center, while the anomalous log sequences have a larger distance

to the center. Meanwhile, another advantage of the spherical objective function is that by making the sequence representations close to the center, the Transformer encoder can also leverage the information from other normal log sequences via the center representation \mathbf{c} , since \mathbf{c} encodes common patterns of normal log sequences. As a result, the model should be able to predict the masked log keys with higher accuracy for normal log sequences because the normal log sequences should share similar patterns.

Finally, the objective function for training the LogBERT is defined as below:

$$\mathcal{L} = \mathcal{L}_{MLKP} + \alpha \mathcal{L}_{VHM}, \quad (9)$$

where α is a hyper-parameter to balance two training tasks.

C. Anomaly Detection

After training, we can deploy LogBERT for anomalous log sequence detection. The idea of applying LogBERT for log anomaly detection is that since LogBERT is trained on normal log sequences, it can achieve high prediction accuracy on predicting the masked log keys if a testing log sequence is normal. Hence, we can derive the anomalous score of a log sequence based on the prediction results on the MASK tokens. To this end, given a testing log sequence, similar to the training process, we first randomly replace a ratio log keys with MASK tokens and use the randomly-masked log sequence as an input to LogBERT. Then, given a MASK token, the probability distribution calculated based on Equation 6 indicates the likelihood of a log key appeared in the position of the MASK token. Similar to the strategy in DeepLog [5], we build a candidate set consisting of g normal log keys with the top g highest likelihoods computed by $\hat{\mathbf{y}}_{[\text{MASK}_i]}^j$. If the real log key is in the candidate set, we treat the key as normal. However, since anomalous log sequences has the different patterns from normal sequences, the true masked log keys in anomalous sequences should have low likelihoods when we use LogBERT that is trained on the normal sequence for prediction. Hence, if the observed log key is not in the top- g candidate set predicted by LogBERT, we consider the log key as an anomalous log key. Then, when a log sequence consists of more than r anomalous log keys, we will label this log sequence as anomalous. Both g and r are hyper-parameters and will be tuned based on a validation set.

IV. EXPERIMENTS

A. Experimental Setup

Datasets. We evaluate the proposed LogBERT on three log datasets, HDFS, BGL, and Thunderbird. Table I shows the statistics of the datasets. For all datasets, we adopt around 5000 normal log sequences for training. The number in the brackets under the column “# Log Keys” indicates the number of unique log keys in the training dataset, which means LogBERT only observes a limited number of log keys for training. In the testing phase, we use a special token to indicate the unobserved log keys.

TABLE I: Statistics of evaluation datasets

Dataset	# Log Messages	# Anomalies	# Log Keys	# of Log Sequences in Test Dataset	
				Normal	Anomalous
HDFS	11,172,157	284,818	46 (15)	553,366	10,647
BGL	4,747,963	348,460	334 (175)	10,045	2,630
Thunderbird-mini	20,000,000	758,562	1,165 (866)	71,155	45,385

- Hadoop Distributed File System (HDFS) [12]. HDFS dataset is generated by running Hadoop-based map-reduce jobs on Amazon EC2 nodes and manually labeled through handcrafted rules to identify anomalies. HDFS dataset consists of 11,172,157 log messages, of which 284,818 are anomalous. For HDFS, we group log keys into log sequences based on the session ID in each log message. The average length of log sequences is 19.
- BlueGene/L Supercomputer System (BGL) [19]. BGL dataset is collected from a BlueGene/L supercomputer system at Lawrence Livermore National Labs (LLNL). Logs contain alert and non-alert messages identified by alert category tags. The alert messages are considered as anomalous. BGL dataset consists of 4,747,963 log messages, of which 348,460 are anomalous. For BGL, we define a time sliding window as 5 minutes to generate log sequences, where the average length is 562.
- Thunderbird [19]. Thunderbird dataset is another large log dataset collected from a supercomputer system. We select the first 20,000,000 log messages from the original Thunderbird dataset to compose our dataset, of which 758,562 are anomalous. For Thunderbird, we also adopt a time sliding window as 1 minute to generate log sequences, where the average length is 326.

Baselines. We compare our LogBERT model with the following baselines.

- Principal Component Analysis (PCA) [2]. PCA builds a counting matrix based on the frequency of log keys sequences and then maps the original counting matrix into a low dimensional space to detect anomalous sequences.
- One-Class SVM (OCSVM) [20]. One-Class SVM is a well-known one-class classification model and can be deployed for log anomaly detection by building a feature matrix based on the normal data [3], [4].
- IsolationForest (iForest) [21]. Isolation forest is an unsupervised learning algorithm for anomaly detection by representing features as tree structures.
- LogCluster [22]. LogCluster is a clustering based approach, where the anomalous log sequences are detected by have long distances to the normal clusters.
- DeepLog [5]. DeepLog is a state-of-the-art log anomaly detection approach. DeepLog adopts recurrent neural network to capture patterns of normal log sequences and further identifies the anomalous log sequences based on the performance of log key predictions.
- LogAnomaly [6]. Log Anomaly is a deep learning-based anomaly detection approach and able to detect sequential and quantitative log anomalies.

Implementation Details. We adopt Drain [23] to parse the log messages into log keys. Regarding baselines, we leverage the package *Loglizer* [11] to evaluate PCA, OCSVM, iForest as well as LogCluster for anomaly detection and adopt the open source deep learning-based log analysis toolkit *LogDeep* to evaluate DeepLog and LogAnomaly¹. For LogBERT, we construct a Transformer encoder by using two Transformer layers. The dimensions for the input representation and hidden vectors are 50 and 256, respectively. The hyper-parameters, including α in Equation 9, m the ratio of masked log keys for the MKLP task, r the number of predicted anomalous log keys, and g the size of top- g candidate set for anomaly detection are tuned based on a small validation set. In our experiments, both training and detection phases have the same ratio of masked log keys m . The code of our implementation are available online².

B. Experimental Results

Performance on Log Anomaly Detection. Table II shows the results of LogBERT as well as baselines on three datasets. We can notice that PCA, Isolation Forest, and OCSVM have poor performance on log anomaly detection. Although these methods could achieve extremely high precision or recall values, they cannot balance the performance on both precision and recall, which lead to extremely low F1 scores. This could be because using the counting vector to represent a log sequence leads to the loss of temporal information from sequences. LogCluster, which is designed for log anomaly detection, achieves better performance than PCA, Isolation Forest, and OCSVM. Meanwhile, two deep learning-based baselines, DeepLog and LogAnomaly, significantly outperform the traditional approaches and achieve reasonable F1 scores on three datasets, which show the advantage to adopt deep learning models to capture the patterns of sequences. Moreover, our proposed LogBERT achieves the highest F1 scores on three datasets with large margins by comparing with all baselines. It indicates that by using self-supervised training tasks, LogBERT can successfully model the normal log sequences and further identify anomalous sequences with high accuracy. Especially, the Transformer encoder used in LogBERT is able to capture the long term dependency among log keys. Meanwhile, the self-supervised training task for minimization the volume of hypersphere can further benefit the model to learn shared common patterns from normal log sequences and improve the accuracy on predicting masked log keys.

Ablation Studies. In order to further understand our proposed LogBERT, we conduct ablation experiments on three log datasets. LogBERT is trained by two self-supervised tasks. We evaluate the performance of LogBERT by only using one training task each time. When the model is only trained by minimizing the volume of hypersphere, we identify anomalous log sequences by computing distances of the log sequence representations to the center of normal log sequences c . If the distance is larger than a threshold, we consider a log sequence is anomalous.

Table III shows the experimental results. We can notice that when only using the task of masked log key prediction to train the model, we can still get very good performance on log anomaly detection, which shows the effectiveness of training the model by predicting masked log keys. We can also notice that even we do not train the LogBERT with the task of the volume of hypersphere minimization, LogBERT achieves higher F1 scores than DeepLog on all three datasets, which shows that compared with LSTM, Transformer encoder is better at capturing the patterns of log sequences. Meanwhile, we can observe that when only training the model for minimizing the volume of hypersphere, the performance is poor. It indicates that only using distance as a measure to identify anomalous log sequences cannot achieve good performance. However, combining two self-supervised tasks to train LogBERT can achieve better performance than the models only trained by one task. Especially, for the HDFS dataset, LogBERT trained by two self-supervised tasks gains a large margin in terms of F1 score (82.32) compared with the model only trained by MLKP (78.09). For BGL and Thunderbird, the improvement of LogBERT is not as significant as the model in HDFS. This could be because the average length of log sequences in BGL (562) and Thunderbird (326) datasets are much larger than the log sequences in HDFS (19). For longer sequences, only predicting the masked log keys can capture the most important patterns of log sequences since there are more mask tokens in longer sequences. On the other hand, for short log sequences, we cannot have many masks tokens. As a result, the task of the volume of hypersphere minimization

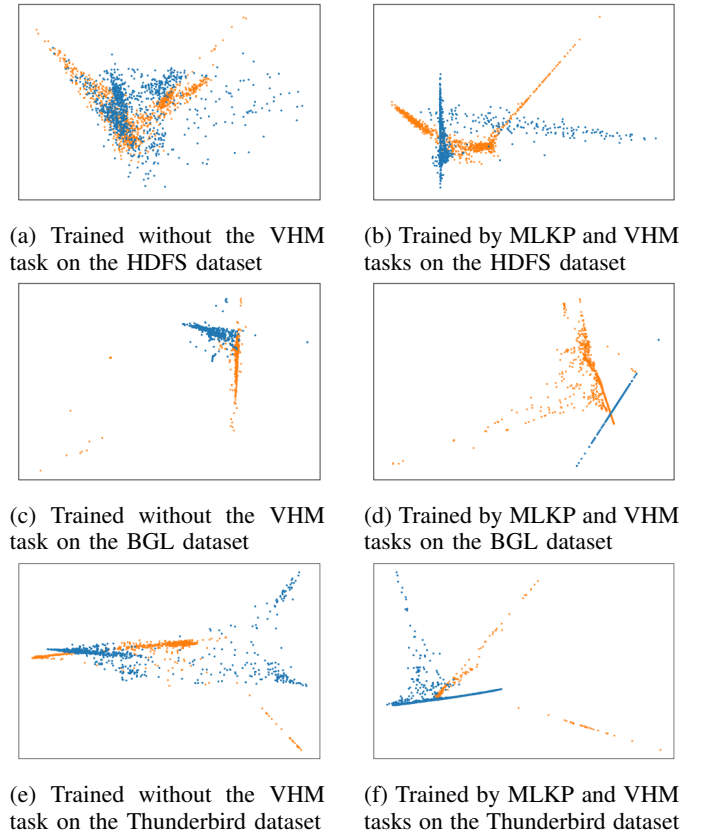

Fig. 3: Visualization of log sequences by using the contextual embedding of DIST tokens h_{DIST} . The blue dots indicate the normal log sequences, while the orange 'x' symbols indicate anomalous log sequences.

can help to boost the performance. Hence, based on Table III, we can conclude that using two self-supervised tasks to train LogBERT can achieve better performance, especially when the log sequences are relatively short.

Visualization. In order to visualize the log sequences, we adopt locally linear embedding (LLE) algorithm [24] to map the log sequence representations into a two dimensional space,

Fig. 4: Parameter analysis on the BGL dataset.

where the contextual embedding of DIST token \mathbf{h}_{DIST} is used as the representation of a log sequence. We randomly select 1000 normal and 1000 anomalous sequences from each dataset for visualization. Figure 3 shows the visualization results of log sequences trained by LogBERT with and without the VHM task. For the HDFS dataset, we can notice that the normal and anomalous log sequences are mixed together when we train the model without the VHM task (shown in Figure 3a). On the contrary, as shown in Figure 3b, by incorporating the VHM task, the normal and anomalous log sequences are clearly separated in the latent space, and the normal log sequences group together. Therefore, as shown in Table III, by incorporating the VHM task for self-supervised training, LogBERT achieves much better performance compared with the model only using the MKLP task on the HDFS dataset. For the BGL and Thunderbird datasets, we can also notice that by using both self-supervised training tasks, the representations of normal sequences are more concentrated (shown in Figures 3d and 3f), which shows the effectiveness of the VHM task. However, different from the HDFS dataset, for the BGL and Thunderbird datasets, the normal and anomalous sequences are relatively separated in the embedding space even without using the VHM task (shown in Figures 3c and 3e). Hence, the performance gain on the BGL and Thunderbird datasets based on both MKLP and VHM tasks is not very significant. Based on the visualization results, we can notice that the VHM task is effective in regulating the distributions of normal sequences. For the short log sequences that do not have enough information, training LogBERT on both tasks can significantly separate the normal and abnormal data in latent space.

Parameter analysis. We adopt the BGL dataset to analyze the sensitivity of model performance by tuning various hyper-parameters. Figure 4a shows that the model performance is relatively stable by setting different α values in Equation 9. This is because, for the BGL dataset, the loss from the masked log key prediction dominates the final loss value due to the long log sequences. As a result, the weight for the VHM task does not have much influence on the performance. Figure 4b shows the performance with different ratios of masked log keys. Note that we use the same ratio of masked log keys in both training and detection phases. We can notice that

increasing the ratios of masked log keys in the sequences from 0.1 to 0.5 can slightly increase the F1 scores while keeping increasing the ratios makes the performance worse. This is because while the masked log keys increase in a reasonable range, the model can capture more information about the sequence. However, if a sequence contains too many masked log keys, it loses too much information from the original log sequences and cannot capture the correlation among log keys as well as the common patterns in normal log sequences for making the predictions. Figure 4c shows that when increasing the size of the candidate set as normal log keys, the precision for anomaly detection keeps increasing while the recall is reducing, which meets our expectation. Hence, we need to find the appropriate size of the candidate set to balance the precision and recall for the anomaly detection.

V. CONCLUSION

Log anomaly detection is essential to protect online computer systems from malicious attacks or malfunctions. In this paper, we have developed LogBERT, a novel log anomaly detection model based on BERT. In order to train LogBERT only based on normal log sequences, we have proposed two self-supervised training tasks. One is to predict the masked log keys in log sequences, while the other is to make the normal log sequences close to each other in the embedding space. After training over normal log sequences, LogBERT is able to detect anomalous log sequences based on the performance on masked log key prediction. Experimental results on three log datasets have shown that LogBERT outperforms the state-of-the-art approaches for log anomaly detection. In the future, we plan to study how to design self-supervised learning tasks for anomaly detection based on unlabeled data. Currently, most of the existing studies are developed based on the one-class dataset. A more challenging task is to achieve the sequential anomaly detection based on an unlabeled dataset that consists of both normal and anomalous log sequences. Furthermore, one interesting fact of training BERT for natural language processing tasks is that by incorporating different tokens in the text data, we can propose various training tasks based on different information. How to design more appropriate self-supervised tasks to further improve the performance of log anomaly detection is also worth to explore.
